Abstract: This paper describes the on-going work done by Hydro-Québec to optimize the settings of automatic devices installed in its main power plants to maintain secure operation under extreme contingencies. The automatic generator tripping and load shedding system (RPTC) described in this paper is installed at the Churchill Falls hydroelectric power plant (5500 MW) in Labrador. Data mining techniques like decision trees (DT) and regression trees (RT) have been used. Real time snapshots of the Hydro-Québec power system collected over a 5 year period have been used to generate large amounts of results by transient stability simulations. The processing of these data has been done using software developed by the University of Liege. This approach gives the most relevant parameters and finds optimal settings for the RPTC system, minimizing the number of tripped generator units while maintaining the same performance in terms of security coverage. New operation rules can thus be established.

kV substations of the Hydro-Québec systems in a same corridor (or main axis) into an independent group. There are a total shown in dark shaded areas in Figure 1. Each RPTC system performs, associated with independent Protection Systems, the generation tripping at particular generation site while the remote load function is centralized. Figure 2 displays the diagram of RPTC. The RPTC system detects the (LOD) or the bypass of series compensation bar the transmission network. According to the location of the extreme contingencies, the Classification Unit (CCU) sends the information generation tripping, the remote load shedding tripping of shunt reactors if required.

1 INTRODUCTION

Operating criteria at Hydro-Québec[1] ensure that the transmission network can support normal contingencies (Table 1) without interruption of electricity and without any assistance of Special Protection Systems (SPS). This set of contingencies is used to determine the secure power transfer limits. They comply with the Northeast Power Coordinating Council (NPCC) criteria.

In addition to these requirements, Hydro-Québec has judged that it is also important for the system to be stable after certain extreme contingencies (Table 1)[2]. The system stability is maintained by a scheme of generator tripping and load shedding, called RPTC, such that transfer limits are not affected. Figure 1 and Figure 2 give an overview of the basic structure and the general operation of the RPTC system. Figure 1 illustrates RPTC systems distributed in fifteen 735

Table 1: Normal contingencies and extreme contingencies

Normal Contingencies	Three phase fault with normal clearing
	Single line to ground fault with delayed clearing
	Breaker fault with normal clearing
	Loss of a bipolar dc line
	Loss of double-circuit line
Extreme Contingencies	Loss of any element without fault
	Single line to ground fault with loss of two series 735 kV line
	Loss of all 735 kV lines emanating from a substation
	Loss of all lines in a corridor
	Loss of two parallel 735 kV lines and bypass capacitors on the remaining line in the same corridor

The tuning of this Special Protection System is complex: the proper level of generation tripping and load shedding must be programmed. There are many configurations to cover and the number of corridors is large. Conventionally, the settings of these RPTC systems were calculated using deterministic techniques cover the worst-case scenarios. Thus, these settings must be optimized with respect to the number of tripped. A probabilistic approach applied to study seems to be particularly interesting.

The study described in this paper covers the RPTC system installed at the Churchill Falls hydroelectric (5500 MW) in Labrador. The purpose of this paper is to optimize the settings of generation tripping and load shedding.

event. In order to extract useful information from the database and to cover a sufficiently diverse set of situations, a large amount of data cases were retrieved from the database where real time power system snapshots are stored. Various network states were simulated using the power system analysis software developed by the Hydro-Québec Research Institute (IREQ). These cases represent actual operating states collected over a 5-year period. By using the data mining technique [3]-[6], the most relevant parameters for this automatic device will be identified and effective settings will be determined.

- o To suggest an algorithm to modulate the number of generation units to trip.

The methodology used is as follows:

- o Extraction of 10 000 network cases spread over a period of 5 years;
- o Filtering of those cases to select only topologies with 3 links between Churchill Falls and Montagnais;
- o Creation of each case with a random fault duration and a random time of bypassing a capacitor;
- o Simulations to find the minimum number of units to be tripped to ensure system stability after this event;
- o Optimization of the number of units to be tripped with a decision tree.

3 DATABASE GENERATION

3.1 Methods for data base generation

The statistical approach used in this work requires the processing of a very large quantity of results generated by numerous scenario simulations. Each scenario is composed of a power flow snapshot of the network with the disturbances described in section 2. The simulations have a 10 second time frame and are performed on a PC network using a transient stability program (Hydro-Québec ST600 program). The approach has to generate pessimistic scenarios in order to cover adequately the critical situations where the RPTC automatic device operates with a good variance on the critical parameters and variables.

Two approaches have been envisioned:

- o In the first approach, the generation of scenarios is done from a limited number of load flow base cases corresponding to real operating situations. These cases are then modified according to certain rules and the corresponding scenarios are simulated in order to create many critical situations for the RPTC system.
- o In the second approach, the scenarios are generated from snapshots of real operating cases taken periodically over a long period of time (years) and disturbances critical for the RPTC system are simulated.

Particular care has to be taken in the generation process to avoid overrepresentation of non-relevant cases.

The results from the first approach are biased due to the overrepresentation of critical situations with in fact very low probability. This could be corrected only if probability data are available on disturbances and/or operating conditions.

Therefore, the second approach, which has been this work, seems more appropriate due to the operating cases used are real.

3.2 Data generation program

As shown in Figure 3, an extraction and a data conversion is first accomplished. The data conversion allows simulations of power system real snapshots for the control center database.

For this task, CILEX [7] software is used. Québec in-house software is widely used snapshots for planning and operation planning.

Figure 3: Data Generation Program

A control software (pData) was developed to generate snapshot cases in order to keep just the relevant ones (cleaning process). For each filtered case, pData builds the disturbance to be simulated as a function of the peculiarities of the studied case.

In this process, pData associates a random value to the parameters of the disturbance in order to take into account the effects of these variations on the results. These are the fault clearing time corresponding to the limit time (breaker operation) and the series compensation time.

From transient stability simulations (Hydro-Québec ST600 program), pData determines, for each case, the minimum number of units to be tripped by an iterative process respecting security criteria.

Finally, pData extracts results and saves some pre-selected relevant parameters, which will be used for mining analysis.

From the 10000 extracted and converted snapshots, pData filter rejected more than half of the cases were, either because the resulting configuration did not have 3 lines connecting at Churchill Falls or data errors caused load flow non-convergence. In the remaining 4600 cases, 13000 load flow and transient stability simulations were run to find the minimum number of units to be tripped. The total simulation duration of the 13000 cases is in the range of 500 CPU hours on a 650 MHz PC.

4 DATA MINING

4.1 Data mining techniques

Data mining refers to the extraction of high-level synthetic information (knowledge) from databases containing large amounts of low-level data. It is also called Knowledge Discovery in Databases (KDD). Data mining has received a wide range of applications in recent decades, for example in medical diagnosis, in character recognition, as well as in financial and marketing problems. The main reason for the important breakthrough is the tremendous increase in computing power. This makes possible the application of the often very computationally intensive data mining algorithms to practical large-scale problems. Nowadays, data mining techniques are also used in solving power system problems such as security assessment [3]-[5].

Table 3: Statistical Data of Unnecessary Tripped units from the Generated Database

# Of Units to Trip	Number Of Cases			Over-tripping		
	With Current Rules	Of Matched Tripping	With Over-tripping	# of Units	Average per case	Rate (%)
8	2130	205	1925	5643	2.65	33
7	647	93	554	1818	2.81	40
6	626	15	611	2288	3.65	61
5	135	0	135	625	4.62	93
4	278	0	278	1047	3.77	94
3	159	0	159	477	3	100
2	157	0	157	314	2	100
1	58	0	58	58	1	100
0	370	370	0	0	0	0
Total	4560	683	3877	12270	2.69	44

Data mining involves an integration of techniques from multiple disciplines such as database technology, statistics, machine learning, high-performance computing, pattern recognition, neural networks and so on. Many methods have been developed in the field of data mining. Here, this paper is focused on using the decision tree type methodology to optimize RPTC system settings for generator tripping in emergency control at Hydro-Québec.

A decision tree (DT) is a map of the reason. This data mining technique is able to produce new, unobserved cases. The DT has the hierarchical structure upside-down and is built on the Learning Set (LS). The LS comprises a number of objects. Each case consists of pre-classified states (described by a certain number of parameters), along with its correct classification (called the goal attribute). The candidate attributes are characterized by the pre-disturbance operating point parameters which can be used to make decision. The building process seeks to build a set of rules that fit the data well enough without over-fitting this data. The test set is tested on a different data set (test set) where the classification of the goal attribute by these rules is compared with the actual class (determined by simulation) for each test case. The classification error rate for the test set measures the success of the method or not.

There are many reasons to use decision trees. Their interpretability. A tree structure provides information of how an output is arrived at. An important asset is the ability of the method to identify the candidate attributes the most relevant parameters for the problem. A last characteristic of decision trees is computational efficiency. The particular decision tree induction method used in this paper is details in [8].

5 RESULTS

5.1 Correlation studies

Using the generated database, correlation studies were performed. Figure 4 shows the correlation of transfer margin on the Churchill Falls corridor generator unit tripping as determined by the simulations. The dashed horizontal line in Figure 4 for example, that the currently used-rules require units if the transfer margin on the Churchill Falls is less than 400 MW (see Table 2). From the database (4560 cases), there are about 2130 cases in which the current rules require 8 units to be tripped. Actually, we can see from Figure 4 that if the transfer margin on the Churchill Falls corridor is less than 3300 MW (vertical line), there is no need to trip generator units. We count the number of cases for which the simulations found that it is necessary to trip 8 units, only 205 cases. Thus, among the 2130 cases in

Figure 4: Correlation of Transfer and Margin at Churchill Falls Corridor

current rules tell us to trip 8 units, there are 1925 cases which need less than eight (down to zero) unit tripping. More synthetically, if we count among these 2130 cases the difference between the number of units required to trip by the current rules and the actual number of units necessary to be tripped according to the simulations, it is found that 33% of generator units (5643 units) are unnecessarily tripped with the currently used 8 units tripping rules.

Table 3 shows some other statistical data from the generated database. It can be observed that among 4560 cases the average of generator units over-tripped is about 2.69 per case and 44% of generator units are over-tripped. From this, it can be seen that the current rules are highly conservative and could possibly be improved by taking into account not only the margin but also the total power transfer through the Churchill Falls corridor in their formulation.

5.2 Applying a 5200 MW limit

Table 2 takes into account the transfer margin (maximum transfer minus measured transfer on the Churchill Falls corridors) to determine the number of units to be tripped. The maximum transfer considers many network configurations (lines, series compensation, synchronous condenser) as well as circuit breaker configurations, but

circuit breaker configurations have no impact or limit for the event used in this study. Therefore used in Table 2 are very conservative. To quick impact of removing this restriction on the number tripped in excess, we have rebuilt the table by account a margin computed on a maximum transfer of 5200 MW. The obtained results are surprising over-tripping to an average value of 1.72 per case from 2.69 with the current rules. However, this cannot be used as it is because it doesn't take certain network configurations having an impact studied here. For these cases, the number of generator units to the tripping is not enough to maintain stable operation.

5.3 Regression tree

Constructions of regression trees were carried out on the generated database using data mining software developed at the University of Liege. Among 4560 cases, 2000 objects were selected as a learning set and the remaining 2560 objects were comprised as a test set. The goal is to predict the minimum number of generator units to be tripped. Figure 5 Shows a constructed regression tree. The tree is to read top-down: each internal node corresponds to a test on one of the candidate attributes and nodes correspond to decisions about the number of generator units to be tripped.

Figure 5: Regression Tree to Predict Number of Generator Unit Tripping

tripped. These nodes are sorted left to right by increasing number of units to be tripped. For example the left-most terminal node (denoted T4) corresponds to 630 cases for which the expected number of units to be tripped is 0.04921. A case will be directed to this node if $T_CHU_MONT < 3912.5$ MW. On the other hand, the right-most terminal node (denoted T42) corresponds to an expected number of units to be tripped of 6.92, for the conditions of $T_CHU_MONT > 4754.5$ MW and $KV_CHU735 > 739.5$ KV. The parameter T_CHU_MONT represents the transfer on the Churchill Fall Corridors and KV_CHU735 is the voltage at the Churchill Falls.

Table 4: Average of Over-tripped Units per Case

Methods Used	Average
Current Rules	2.69
Margin Based on 5200 MW limits	1.72
Combination of Transfer and Margin	1.48
Regression Tree with Post-processing	1.01

Notice that among the 236 candidate attributes proposed to the tree building software, only 7 attributes were identified as important variables to decide on the number of units to be tripped. Notice also that in order to translate the rules provided by the tree into decision rules it is obviously necessary to convert the fractional predictions into integer numbers (e.g. by rounding up to the nearest larger integer

value – ceiling function).

By construction, the predictions of the regression tree are unbiased estimates of the true values; this means errors are both negative and positive. In practice it is preferable to have rules which have less negative errors (few unit tripping – under-tripping) than positive errors (many unit tripping – over-tripping) because the cost of installing more units is higher than the cost of unnecessarily tripping one unit. Such a bias can be introduced as a post-processing step on the regression tree output, for example by adding a positive constant to its predictions before rounding to the nearest integer.

5.4 Comparison of results

Table 4 lists the average of over-tripped units per case. Although this value may not have a direct physical meaning, it is used here as an indication of the improvement of different methods tested. The first line of the table shows the rules actually in use, and designed by a deterministic method. The second line shows the results of a modification of these rules when a constant transfer limit of 5200MW is used to compute the margin. The third line shows the performance of another rule designed by hand, taking into account both margin and transfer limit. Finally, the last line shows the results of the regression tree with post-processing.

line gives the results obtained by rules of a post-processing of the regression tree of Figure 5. This post-processing consists in adding a positive bias of 0.45 to the predictions of the tree and round up to the nearest integer (ceiling function). It can be seen that the regression tree has the least average value of over-tripped generator units per case. This means that if the regression tree rules are implemented, the number of generator unit tripping will be closest to their minimum among all other methods.

Figure 6 shows the frequency diagram of mis-tripped generator units for different methods. The term of "mis-tripped" unit is defined as the difference between simulated optimal unit tripping and non-simulated unit tripping. A positive value means generator units are over-tripped while negative value means under-tripped. The distribution of mis-tripped units by the current rules is widely spread while that of the regression tree is concentrated. In most cases, the regression tree gives one generator unit over-tripping while the current rules sometimes gives 8 generator units over-tripping. The reason that the regression tree mis-tripping is concentrated around one is, as mentioned previously, that the post-processing is applied to the regression tree of Figure 5. This post-processing adds a positive value of 0.45 to the predictions of the tree before applying the ceiling function in order to eliminate most of the generator unit under-tripping. Therefore, it appears that in most cases the regression tree settles on one generator unit over-tripping. The results from the regression tree are very promising, but more efforts have to be made to assess whether the risk of under-tripping is acceptable (with respect to other risks not taken into account in our study), and if not, to eliminate the few remaining cases of under-tripping.

6 CONCLUSIONS

The study described in this paper covers the RPTC automatic device installed at the Churchill Falls hydroelectric power station (5500 MW) in Labrador. The data mining technique was applied to the results of some 13000 network simulations. Various network states were taken from a real-time database and were simulated using the network analysis software developed by Hydro-Québec Research Institute (IREQ). The data cases represent actual operating states collected over a 5-year period. By using the data mining technique, the most relevant parameters for this automat were identified and effective settings were determined.

A correlation analysis and the construction of regression trees were carried out on the results of these simulations using data mining software developed at the University of Liege. This analysis made it possible to minimize, in particular, the number of generators tripped by the RPTC system for a large number of network conditions, while maintaining the same

performance in terms of security coverage. New rules can thus be established and will be implemented.

Following these very encouraging results, applications of these methods are being considered in Québec in the coming years.
